CLINICAL NOTES

- None

NEXT STEPS

- Carrier testing should be considered for the diseases specified above for the patient's partner, as both parents must be carriers before a child is at high risk of developing the disease.
- Genetic counseling is recommended and patients may wish to discuss any positive results with blood relatives, as there is an increased chance that they are also carriers.

What is Polyglandular Autoimmune Syndrome Type 1?

Polyglandular Autoimmune Syndrome Type 1 (PAS-1) is an inherited disease in which the body's immune system mistakenly attacks healthy cells, notably the glands that produce the body's hormones. People with PAS-1 have at least two of the disease's main symptoms: fungal infections of the skin and mucous membranes, decreased function in the parathyroid glands, and decreased function in the adrenal glands (Addison disease). Many people with the disease have all three main symptoms. There are also numerous and diverse other symptoms which can occur.

In the majority of people with PAS-1, the first symptom to appear is recurrent and persistent fungal infections of the skin and mucous membranes, such as the in the moist lining of the nose and mouth. These infections typically begin between the ages of 3 and 5, although they can occur any time before one's 30s.

Frequently the second symptom of the disease to appear is an underactive parathyroid gland (hypoparathyroidism). This typically occurs before the age of 10. The parathyroid glands normally secrete a hormone used to regulate the amount of calcium and phosphorous in the bone and blood. An underactive parathyroid gland can cause numerous symptoms including tingling in the lips, fingers, and toes; muscle cramps; pain in the abdomen, face, legs, and feet; weakness or fatigue; and dry hair and skin.

Often the third symptom to appear is underactive adrenal glands, a condition known as Addison disease. This disease typically appears before the age of 15. Addison disease can cause fatigue, muscle weakness, weight loss, low blood pressure, and changes in skin coloration.

There are numerous other symptoms which can also occur in people with PAS-1. These include chronic liver disease, extreme fatigue due to a problem with red blood cells, skin disease, total body hair loss, an underactive pituitary gland, abnormalities in the ovaries and testes, diarrhea, difficulty absorbing nutrients from food, and eye problems, among others.

The most common pattern with PAS-1 is that the three main symptoms of the disease—fungal infections of the skin, underactive parathyroid gland, and Addison disease—develop in that order before the age of 20. The other symptoms associated with the disease may then begin sporadically over time until one's 50s, when the symptoms typically stabilize. This does not hold true for all people with PAS-1, however. Generally speaking, the earlier in life that the main symptoms appear, the more likely it is that additional symptoms will develop.

How common is Polyglandular Autoimmune Syndrome Type 1?

PAS-1 is a rare condition in the United States, but it is more common among certain ethnic groups. The number of people affected include:

- Iranian Jews: 1 in 6,500 to 9,000
- Sardinians: 1 in 14,000
- Finns: 1 in 25,000
- Slovenians: 1 in 43,000
- Norwegians: 1 in 80,000 to 90,000
- Poles: 1 in 129,000

How is Polyglandular Autoimmune Syndrome Type 1 treated?

There is no cure for PAS-1. Each symptom must be treated as it arises and lifelong regular checkups are necessary to look for any new symptoms. It is important to discover and treat new symptoms as soon as possible to prevent permanent damage to the body.

Physicians often prescribe hormone replacement therapy or intravenous steroids for people with PAS-1. Calcium and vitamin D are often helpful to treat an underactive parathyroid gland. Fungal infections can be treated with medication.

Other symptoms are treated as they arise. For example, people with diabetes can take insulin and monitor their diet.

What is the prognosis for a person with Polyglandular Autoimmune Syndrome Type 1?

The prognosis for a person with PAS-1 varies depending on the number and severity of his or her symptoms. Early detection of the disease and its component symptoms is important for preventing life-threatening scenarios. With careful monitoring, it is possible to have a normal or near-normal lifespan. Women with PAS-1 can give birth, and men with PAS-1 can father healthy children.

Methods and Limitations

DONOR 10298 [Foresight Carrier Screen]: Sequencing with copy number analysis, spinal muscular atrophy, and analysis of homologous regions.

Sequencing with copy number analysis

High-throughput sequencing and read depth-based copy number analysis are used to analyze the listed exons, as well as selected intergenic and intronic regions, of the genes in the Conditions Tested section of the report. The region of interest (ROI) of the test comprises these regions, in addition to the 20 intronic bases flanking each exon. In a minority of cases where genomic features (e.g., long homopolymers) compromise calling fidelity, the affected intronic bases are not included in the ROI. The ROI is sequenced to high coverage and the sequences are compared to standards and references of normal variation. More than 99% of all bases in the ROI are sequenced at greater than the minimum read depth. Mutations may not be detected in areas of lower sequence coverage. Small insertions and deletions may not be as accurately determined as single nucleotide variants. Genes that have closely related pseudogenes may be addressed by a different method. *CFTR* and *DMD* testing includes analysis for both large (exon-level) deletions and duplications with an average sensitivity of 99%, while other genes are only analyzed for large deletions with a sensitivity of >75%. However, the sensitivity may be higher for selected founder deletions. If *GJB2* is tested, two large upstream deletions which overlap *GJB6* and affect the expression of *GJB2*, del(*GJB6*-D13S1830) and del(*GJB6*-D13S1854), are also analyzed. Mosaicism or somatic variants present at low levels may not be detected. If detected, these may not be reported.

Detection rates are determined by using literature to estimate the fraction of disease alleles, weighted by frequency, that the methodology is unable to detect. Detection rates only account for analytical sensitivity and certain variants that have been previously described in the literature may not be reported if there is insufficient evidence for pathogenicity. Detection rates do not account for the disease-specific rates of de novo mutations.

All variants that are a recognized cause of the disease will be reported. In addition, variants that have not previously been established as a recognized cause of disease may be identified. In these cases, only variants classified as "likely" pathogenic are reported. Likely pathogenic variants are described elsewhere in the report as "likely to have a negative impact on gene function". Likely pathogenic variants are evaluated and classified by assessing the nature of the variant and reviewing reports of allele frequencies in cases and controls, functional studies, variant annotation and effect prediction, and segregation studies. Exon level duplications are assumed to be in tandem and are classified according to their predicted effect on the reading frame. Benign variants, variants of uncertain significance, and variants not directly associated with the intended disease phenotype are not reported. Curation summaries of reported variants are available upon request.

Spinal muscular atrophy

Targeted copy number analysis is used to determine the copy number of exon 7 of the *SMN1* gene relative to other genes. Other mutations may interfere with this analysis. Some individuals with two copies of *SMN1* are carriers with two *SMN1* genes on one chromosome and a *SMN1* deletion on the other chromosome. This is more likely in individuals who have 2 copies of the *SMN1* gene and are positive for the g.27134T>G SNP, which affects the reported residual risk; Ashkenazi Jewish or Asian patients with this genotype have a high post-test likelihood of being carriers for SMA and are reported as carriers. The g.27134T>G SNP is only reported in individuals who have 2 copies of *SMN1*.

Analysis of homologous regions

A combination of high-throughput sequencing, read depth-based copy number analysis, and targeted genotyping is used to determine the number of functional gene copies and/or the presence of selected loss of function mutations in certain genes that have homology to other regions. The precise breakpoints of large deletions in these genes cannot be determined, but are estimated from copy number analysis. High numbers of pseudogene copies may interfere with this analysis.

If *CYP21A2* is tested, patients who have one or more additional copies of the *CYP21A2* gene and a loss of function mutation may not actually be a carrier of 21-hydroxylase-deficient congenital adrenal hyperplasia (CAH). Because the true incidence of non-classic CAH is unknown, the residual carrier and reproductive risk numbers on the report are only based on published incidences for classic CAH. However, the published prevalence of non-classic CAH is highest in individuals of Ashkenazi Jewish, Hispanic, Italian, and Yugoslav descent. Therefore, the residual and reproductive risks are likely an underestimate of overall chances for 21-hydroxylase-deficient CAH, especially in the aforementioned populations, as they do not account for non-classic CAH. If *HBA1*/*HBA2* are tested, some individuals with four alpha globin genes may be carriers, with three genes on one chromosome and a deletion on the other chromosome. This and similar, but rare, carrier states, where complementary changes exist in both the gene and a pseudogene, may not be detected by the assay.

Limitations

In an unknown number of cases, nearby genetic variants may interfere with mutation detection. Other possible sources of diagnostic error include sample mix-up, trace contamination, bone marrow transplantation, blood transfusions and technical errors. This test is designed to detect and report germline alterations. While somatic variants present at low levels may be detected, these may not be reported. If more than one variant is detected in a gene, additional studies may be necessary to determine if those variants lie on the same chromosome or different chromosomes. The test does not fully address all inherited forms of intellectual disability, birth defects and genetic disease. A family history of any of these conditions may warrant additional evaluation. Furthermore, not all mutations will be identified in the genes analyzed and additional testing may be beneficial for some patients. For example, individuals of African, Southeast Asian, and Mediterranean ancestry are at increased risk for being carriers for hemoglobinopathies, which can be identified by CBC and hemoglobin electrophoresis or HPLC (*ACOG Practice Bulletin No. 78. Obstet.Gynecol. 2007;109:229-37*).

Risk Calculations

Below are the risk calculations for all conditions tested. Since negative results do not completely rule out the possibility of being a carrier, the **residual risk** represents the patient's post-test likelihood of being a carrier and the **reproductive risk** represents the likelihood the patient's future children could inherit each disease. These risks are inherent to all carrier screening tests, may vary by ethnicity, are predicated on a negative family history and are present even after a negative test result. Inaccurate reporting of ethnicity may cause errors in risk calculation. The reproductive risk presented is based on a hypothetical pairing with a partner of the same ethnic group.

†Indicates a positive result. See the full clinical report for interpretation and details.
